Received: date / Accepted: date

Abstract The allocation of emergency responders to rescue tasks is a key application area for agent-based coordination algorithms. However, to date, none of the proposed approaches take into account the inherent uncertainty in disaster scenarios and, crucially, none have been field-trialled in order to understand how humans perform when instructed by an agent. Hence, in this paper, we propose a novel representation and an algorithm, using Multi-agent Markov Decision Processes, to solve the problem of coordinating emergency responders in uncertain environments. Moreover, we deploy our algorithm in a mixed-reality game called AtomicOrchid, with an agent that works alongside a human commander to guide human players to complete rescue tasks. In our trials, our algorithm is shown to improve performance significantly (compared to a no-agent setting) and our results allow us to elucidate some of the key challenges faced when developing systems involving human-agent collaboration.

1 Introduction

The coordination of teams of first responders in search and rescue missions is a grand challenge for multi-agent systems research [21]. In such settings, responders with different capabilities (e.g., fire-fighting or life support) have to form teams in order to perform rescue tasks (e.g., extinguishing a fire or providing first aid) to minimise loss of life and costs (e.g., time or money). Thus, responders have to plan their paths to the tasks (as these may be distributed in space) and form specific teams to complete them. These teams, in turn, may need to disband and reform in different configurations to complete new tasks, taking into account the status of the current tasks (e.g., health of victims or building fire) and the environment (e.g., if a fire or radioactive cloud is spreading). Furthermore, uncertainty in the environment (e.g., wind direction or speed) or in the responders' abilities to complete tasks (e.g., some may be tired or get hurt) means that plans are likely to change continually to reflect the prevailing assessment of the situation.

To address these challenges, a number of algorithms and mechanisms have been developed to form teams and allocate tasks. For example, [40,45] and [10], devised centralised and decentralised optimisation algorithms respectively to allocate rescue tasks efficiently to teams of first responders with different capabilities. However, none of these approaches considered the inherent uncertainty in the environment or in the first responders' abilities. Crucially, to date, while all of these algorithms have been shown to perform well in simulations (representing responders as computational entities), none of them have been *exercised* to guide *real* human responders in real-time rescue missions. Thus, it is still unclear whether these algorithms will cope with real-world uncertainties (e.g., communication breakdowns or changes in wind direction), be acceptable to humans (i.e., be clear for humans and take into account their capabilities), and actually augment, rather than hinder, human performance.

[[make sure all these references are ported to the background section]] [[add other related work from HCI here as well as RoboCupRescue]]

Against this background, we develop a novel algorithm for team coordination under uncertainty and evaluate it within a real-world mixed-reality game that embodies the simulation of team coordination in disaster response settings. In more detail, we consider a scenario involving rescue tasks distributed in a physical space over which a (virtual) radioactive cloud is spreading. Tasks need to be completed by the responders before the area is completely covered by the cloud (as responders will die from radiation exposure) which is spreading according to varying wind speed and direction. Our algorithm captures the uncertainty in the scenario (i.e., in terms of environment and player states) and is able to compute a policy to allocate responders to tasks that minimises task completion time and ensures responders are not exposed to significant radiation. The algorithm is then used by an agent to guide human responders. Specifically, it is integrated into our test platform, AtomicOrchid, that structures the interaction between human responders, a human commander, and the planning agent in a mixed-reality location-based game. By so doing, we are able to study, both quantitatively and qualitatively, the performance of a human-agent collective (i.e., a mixed-initiative team where control can shift between humans and agents) and the interactions between the different actors in the system. In particular, we advance the state of the art in the following ways:

1. We develop a novel representation [[better: mechanism (?)]] for team coordination (i.e., path planning and task allocation) under uncertainty using Multi-agent Markov Decision Processes (MMDP) [6]. Moreover, we provide an algorithm to approximate

solutions to the MMDP and show how it is adaptive to human requests to re-plan task allocations within a team. **[[added the following to make connection clear:]]** We embed the mechanism to drive a planning support agent in the AtomicOrchid game to evaluate it with users in a real-world setting.

- 2. We present AtomicOrchid, a mixed-reality game to evaluate team coordination under uncertainty, focusing particularly on human-agent collaboration. In AtomicOrchid, human players in the field are supported by our planning agent in their mission to coordinate rescue tasks efficiently by communicating with headquarters and each other via the Mobile Responder App.
- 3. Thus, we provide a real-world evaluation of our planning support agent that instructs field responders through mobile messages in a disaster response scenario in multiple field trials and present both quantitative and qualitative results.

When taken together, our results show, for the first time, how agent-based coordination algorithms for disaster response can be integrated and validated with human teams. Moreover, these results allow us to derive a methodology and guidelines to for systems involving human-agent collaboration.

The rest of this paper is structured as follows. Section 3 formalises the disaster response problem as a MMDP. Section 4 describes the algorithm to solve the path planning and task allocation problems presented by the MMDP. Section 5 details the AtomicOrchid platform. Section 6 presents our pilot study and the field trial evaluation. Finally, Section 7 concludes.

2 Background

In this section we discuss related work and provide a short background on the techniques used in this paper. As our work lies at the intersection between Multi-Agent Coordination and Human-Computer Interaction (HCI) for disaster management applications, we discuss relevant algorithms for multi-agent coordination to support emergency responders and then describe the HCI techniques and approaches for the same purpose. We then go on to discuss the challenges relevant to human-agent collaboration and then justify our use of mixed-reality games to evaluate this form of collaboration. Through our analysis we also identify the challenges that pertain to the coordination of human emergency responders under significant uncertainty and therefore, conclude with some background on decision-theoretic approaches to solving the coordination problem under uncertainty.

2.1 Human Team Coordination for Disaster Response

Team coordination focuses on managing interdependencies between activities performed by individual team members to achieve the team's goal [28]. In emergency response failures in team coordination can often occur due to the complexities of such interdependencies, and such failures are widely acknowledged as the most significant factor that can cost human lives [51, p. 2]. In particular, related work studies the challenges that arise when team members aim to create a shared understanding (e.g., of what needs to be done) [12], develop situation awareness (i.e., knowledge of the environment and the actors within it), and align cooperative action through on-going communication.

Moreover, we note the work of [11] that highlighted that one important characteristic of large-scale disasters is the presence of multiple spatially distributed incidents. To deal with multiple incidents, the disaster response team has to coordinate spatially distributed

resources and personnel to carry out operations (e.g. search, rescue, and evacuation). Therefore, it is necessary to optimise the coordination of teams by allocating tasks to teams in time and space efficiently and sufficiently. Thus, a number of tools and system architectures have been developed to support such team coordination [30] [35] [12]. However, while these approaches focus on providing tools to human teams, a number of agent-based solutions have been developed in the last few years to better guide human emergency responders. We elaborate on such solutions next.

2.2 Agents for Disaster Response

Kitano et al [21] were the first to propose disaster response as a key application area for multi-agent systems. Since then, a number of algorithms and simulation platforms have been developed to solve the computational challenges involved. For example, algorithms have been developed to efficiently allocate emergency responders to rescue tasks (e.g., to rescue civilians, extinguish fires, or unblock roads) for (i) decentralised coordination: where emergency responders need to chose their actions based on local knowledge [10,38], (ii) coordination by a central authority: where a command centre is able to choose actions for all the members of the team given complete knowledge of the system [24,45,20], and (iii) coalition formation: where sub-teams can perform tasks with different levels of efficiency, as defined by the synergies between their capabilities (e.g., when two policemen help rescue a civilian from rubble they would be less effective than a fire and rescue officer and a medic) [?]. Many of these algorithms are actually evaluated in simulation using the the RoboCupRescue disaster simulation platform [49]. In this platform, emergency response tasks are modelled computationally (e.g., functions describing speed and efficiency of agents at completing tasks) and the emergency responders are modelled as agents that automatically implement the outputs of a given task allocation algorithm [22,40]. While such evaluations are useful to determine extreme scenarios (e.g., best case when all agents implement all tasks perfectly or worst case when they do not), they are prone to misrepresentations of human decision making. Hence, we next discuss approaches to human teaming in disaster response.

2.3 Challenges for Human Agent Collaboration

Many multi-agent agent coordination algorithms have potential to be applied to support task assignment of responder teams. However, before we use those algorithms to build agent planning support system, there is a need to understand how human and agent can effectively collaborate. Human factors researchers have conducted controlled experiments to identify key aspects of human agent collaboration [9][34] [50] [52] and evaluate strategies of agent support for teams [27]. Prior research has recognised that interaction design is vital for the performance of socio-technical human-agent systems [32], particularly where an agent directly instructs humans [31]. With inappropriate interaction design, agent-based planning support may function inefficiently, or at worst, hinder the performance of human teams. Although there is much literature in planning support, task assignment, and human-agent collaboration, Yet, real world studies of how human teams handle agent support are rare.

Moverover, [8] have shown that an ill-designed work-flow management/automation system can lead to undesirable results, not only fail to improve work efficiency but also hinders

human performance. Bowers et al. found that extreme difficulties might be encountered when introducing new technology support for human teams. It turns out that new technologies might not support, but disrupt smooth workflow if they are designed in an organisationally unacceptable way [1]. We believe the same is true for intelligent planning support. Before we can build intelligent systems that support human team coordination, we believe it is crucial to run field trials to understand the potential impact of technology support for team coordination (as we show in this paper – see Section ??). In particular, in this work, we turn to the use of gamification to run such trials.

2.4 Disaster Simulation and Games

Computational simulations, particularly agent-based simulations, are the predominant approach in the computing literature to predict the consequences of certain courses of action in disasters [19], to model information flow among first responders [44], or to model the logistic distribution of emergency relief supplies [26].

The limitations of computational simulations are manifold. For example, Simonovic highlights that simulations may rely on unrealistic geographical topography, and most importantly, may not "account for human psychosocial characteristics and individual movement, and (...) learning ability" [48]. The impact of emotional and physical responses likely in a disaster, such as stress, fear, exertion or panic [14] remains understudied in approaches that rely purely on computational simulation.

In our study, we adopt a serious mixed-reality game approach to provide a setting in which people experience realistic cognitive and physical stress [16]. Mixed-reality games are recreational experiences that make use of pervasive technologies such as smart phones, wireless technologies and sensors with the aim of blending game events into a real world environment [4]. Arguably, they have become an established vehicle to explore socio-technical issues in complex real world settings [13]. The major advantage of mixed-reality games is the fact that they are situated in the real world, which arguably leads to increased efficacy of the behavioural observations when compared to computational simulations.

Now, in order to develop agent-based coordination algorithms that are fit to be trialled in real-world mixed-reality games, we note that none of the approaches discussed above (in Section ??) take into account the underlying uncertainty of complex human activities. Hence, in this paper, we turn to decision-theoretic planning to handle such uncertainties. We discuss this framework and potential solution approaches next.

2.5 Background on Decision-Theoretic Multi-Agent Planning

Decision theoretic planning is typically solved using Markov Decision Processes [?]. A *Markov decision process* (MDP) is a mathematical framework for sequential decision making under uncertainty where the problem is specified as a set of states and transition functions (specifying links between these states based on the actions taken). Then, the solution to an MDP specifies what action should be taken in each state given the possible transitions from a given state. In the presence of multiple agents, this model has been extended to *multi-agent*

MDP (MMDP) [6] where the action chosen at any state consists of individual action components performed by the agents. Theoretically, any algorithm such as linear programming, value iteration, or policy iteration that can solve MDPs can also be used to solve MMDPs. However, these are likely to be very inefficient because the action space grows exponentially with the number of agents. In an attempt to combat this complexity, To [7] show how domain structure can be exploited and thus introduced the factored MDP (FMDP) in which the state space is described by a set of variables and the transition model is defined by a dynamic Bayesian network (DBN). When the agents can only observe partial information about the state, this problem can be modelled by multi-agent partially observable MDPs (MPOMDP) [39]. Similar to MMDP, MPOMDP can be treated as an extension of singleagent POMDP to multi-agent domains. This analogy is useful because MPOMDPs can be solved as belief-state MMDPs where a belief state is a probability distribution over the states. All the above models assume that there is a centralised unit that will select a joint action for the team and distribute each action component to the corresponding agent. Decentralised POMDP (DEC-POMDP) [5] is a more general model where the agents are controlled in a decentralised manner. In other words, there is no centralised unit for distributing the actions and each agent must choose its own action based on the local observation.

In this paper, we restrict ourself to model our problem as the MMDP because other models do not fit the characteristic of our domain or are too difficult to be solved with the size of our problem. Specifically, in our domain, we consider a central controller (at headquarters) that will collect all the information and distribute the commands to each filed responder. Therefore, it is not necessary to assume that the information is only partial (as in MPOMDPs) or the decision must be made locally by the responders (as in DEC-POMDPs). Furthermore, those models are much harder than MMDPs and the existing algorithms can only solve very small problems. Moreover, we do not use the FMDP because most of the algorithms for solving this model as it requires that the value function can be factored additively into a set of localized value functions [25, 17, 18] and our problem does not have such structures. For example, in our domain, several tasks may depend on the same responder. If she is delayed in one task, this may affect the completion of the other tasks. In other words, the completion of one task may depend on the completion of the other tasks, and so, the value function can not be factored on the basis of the local task states. Our settings are also different from the one in [10] where they assume that the responders are self-interested and need to negotiate with each other on the task that they want to perform next.

As discussed above, any algorithm that can solve large MDPs can be used to solve MMDPs. However, most of the existing approaches are offline algorithms (see the most recent survey [29] for more detail). The main disadvantage of offline algorithms is that they must compute a complete action mapping for all possible states in the policy. This is intractable for problems with huge state space as in our domain. In contrast to offline approaches, online algorithms interleave planning with execution and only need to compute the best action for the current state instead of the entire state space. Specifically, we adopt the basic framework of Monte-Carlo tree search (MCTS) [23], which is currently the leading online planning algorithm for large MDPs, and divide our online algorithm into two levels: task planning and path planning. It is worth pointing out that our method is different from the hierarchical planning for MMDPs [33] because it requires the task hierarchy to be part of the model and our problem does not have such task hierarchy for the responders. Indeed, our problem is more closely related to the coalition formation with spatial and temporal constraints (CFST) problem where agents form coalitions to complete tasks, each with different demands. However, existing work on CFST often assumes that there is no uncertainty on the agents' actions and the environment [40].

3 The Disaster Scenario

We consider a disaster scenario in which a satellite, powered by radioactive fuel, has crashed in a sub-urban area. Debris is strewn around a large area, damaging buildings and causing accidents and injuring civilians. Moreover, radioactive particles discharged from the debris are gradually spreading over the area, threatening to contaminate food reserves and people. Hence, emergency services (including medics, soldiers, and fire-fighters) are deployed to evacuate the casualties and key assets (e.g., food reserves, medication, fuel), each requiring different teams of responders, before they are engulfed by the radioactive cloud. In what follows, we first model this scenario formally. Second, we describe the use of a planning agent at headquarters to help coordinate the team. Third, we formalise the optimisation problem the human-agent team faces (i.e., including fire-fighters, medics, and soldiers) in trying to save as many lives and assets as possible.

3.1 Formal Model

Let G denote a grid overlaid on top of the disaster space, and assume the satellite debris, casualties, assets, and actors are located at various coordinates $(x, y) \in G$ in this grid. The radioactive cloud induces a radioactivity level $l \in [0, 100]$ at every point it covers (100 corresponds to maximum radiation and 0 to no radiation). While the exact radiation levels can be measured by responders on the ground (at a given location) using their geiger counter, we assume that additional information is available from existing sensors in the area.² However, this information is uncertain due to the poor positioning of the sensors and the variations in wind speed and direction (we show how this uncertainty is captured in the next section). A number of safe zones $G'\subseteq G$ are defined where the responders can drop off assets and casualties (i.e., targets to be rescued). Let the set of first responders be denoted as $I = \{p_1, \dots, p_i, \dots, p_n\}$, where |I| = n and the set of targets to be rescued (i.e., rescue tasks) be denoted as $T = \{t_1, \dots, t_j, \dots, t_m\}$, where |T| = m. A rescue task is performed by picking the target up, carrying it to a safe zone, and dropping it off. As responders perform rescue tasks, they may become tired, get injured, or receive radiation doses that may, at worst, be life threatening. Hence, we assign each responder a health level $h_i \in [0, 100]$ that decreases based on its radiation dose (h_i is decreased by $0.02 \times l$ per second given a radiation level l) and assume that its decision to pick up and carry the target allocated to it is liable to some uncertainty (e.g., they may not want to pick a target because it is too far away or it is unclear how long it is going to take them to carry it back to a safe zone). Moreover, let Θ denote the types of responders (e.g., fire brigade, soldier, or medic) and assume a responder's type determines the capabilities she has and therefore the tasks she can perform. We denote as $\theta_i \in \Theta$ the type of responder p_i . In turn, to complete a given task t_j , a set of responders $C\subseteq I$ with specific types $\Theta_{t_j}\subseteq\Theta$ is required to pick up t_j . Thus, a task can only be completed by a team of responders C_i if $\{\theta_i|p_i\in C_i\}=\Theta_{t_i}$. Given the distribution of responders across the physical space, different sub-teams will perform to different levels (as they have to travel different distances) and this poses a challenge for the commander and to find the best teams needed to perform the tasks.

¹ Given the invisibility of radiation, it is possible to create a believable and challenging environment for the responders to solve in our mixed-reality game (see Section 5).

² This assumption is not central to our problem and only serves to inform the decision making of the agent as we see later. It is also possible to obtain similar information about radiation levels by fusing the responders' geiger counter readings, but this is beyond the scope of the paper.

3.2 Human-Agent Collaboration

In line with practice in many countries, we assume that the first responders are coordinated from a headquarters (HQ) headed by a human coordinator H. In our case, H may be assisted by an autonomous task planning agent PA (more details in Section 4), that can receive input from, and direct, the first responders. Both H and PA can communicate their instructions (task plans to pick up targets) directly to the responders using an instant messaging system (or walkie talkie). While these instructions may be in natural language for H, PA instructs them with simple requests such as "Pick up target X at position Y with team-mates Z" messages. In turn, the responders may not want to do some tasks (for reasons outlined above) and may therefore simply accept or reject the received instruction from PA or H. However, H can query the responders' decisions and request more information about their status (e.g., fatigue or health) and goals (e.g., meeting with team-mate at position X or going for task Y). Instead, if a task is rejected by the responders, PA records this as a constraint on its task allocation procedure (see details in Section 4.1.3) and returns a new plan. Thus on the one hand, richer interactions are possible between H and the first responders than between them and PA. On the other hand, PA runs an sophisticated task allocation algorithm that can compute an efficient allocation, possibly better than the one computable by H (particularly when many responders need to be managed).

It is important to note that our model captures different types of flexible control: (i) agent-based: when PA directly instructs the responders and they can use multiple iterations of accept/reject to collaboratively converge to a definite plan (ii) human-based: when H communicates goals to the responders in open-ended interactions that may permit H to gain a better understanding of the context than PA and therefore formulate corrective measures faster. Moreover, in contrast to previous work that suggested transfer-of-control regimes [46], our approach does not constrain transfers of control to target specific decision points in the operation of the system. Rather, our interaction mechanisms are designed (see Section 5) to allow human control at any point (and our results in Section 6 validate this approach).

3.3 The Optimisation Problem

Previous agent-based models for team coordination in disaster response typically assume deterministic task executions and environments [40,45]. However, in order to evaluate agent-guided coordination in a real-world environment, it is important to consider uncertainties due to player behaviours and the environment (as discussed in the previous section). Given this, we propose a new representation for the task allocation problem in disaster response that does take into account such uncertainties. More specifically, we represent this problem using an MMDP that captures the uncertainties of the radioactive cloud and the responders' behaviours. We model the spreading of the radioactive cloud as a random process over the disaster space and allow the actions requested from the responders to fail (because they decline to go to a task) or incur delays (because they are too slow) during the rescue process. Thus in the MMDP model, we represent task executions as stochastic processes of state transitions, while the uncertainties of the radioactive cloud and the responders' behaviours can be easily captured with transition probabilities. More formally, the MMDP is represented by tuple $\mathcal{M} = \langle I, S, \{A_i\}, P, R \rangle$, where $I = \{p_1, p_2, \cdots, p_n\}$ is the set of actors as defined

³ While some agencies may be trained to obey orders (e.g., military or fire-fighting), others (e.g., transport providers or medics) may not be trained to do so.

in the previous section, S is the state space, A_i is a set of responder p_i 's actions, P is the transition function, and R is the reward function. In the MMDP, the state is Markovian and represents all the information that is sufficient for the agent to make decision. The transition function models the dynamics of the system and how it reacts to the responders' actions. The reward function specifies the objective of the system (e.g., saving as many lives as possible). We elaborate on each of these below.

In more detail, $S = S_r^G \times S_{p_1} \times \cdots \times S_{p_n} \times S_{t_1} \times \cdots \times S_{t_m}$ where:

- $S_r^G = \{l_{(x,y)} | (x,y) \in G\}$ is the state variable of the radioactive cloud that specifies the radioactive level $l_{(x,y)} \in [0,100]$ at every point $(x,y) \in G$.

 $S_{p_i} = \langle h_i, (x_i, y_i), t_j \rangle$ is the state variable for each responder p_i that specifies her
- $S_{p_i} = \langle h_i, (x_i, y_i), t_j \rangle$ is the state variable for each responder p_i that specifies her health level $h_i \in [0, 100]$, her present position (x_i, y_i) , and the task t_j she is carrying out, which is null when she has no task.
- $S_{t_j} = \langle \mathtt{st_j}, (x_j, y_j) \rangle$ is then the state variable for task t_j to specify its status $\mathtt{st_j}$ (i.e., the target is picked up, dropped off, or idle) and position (x_j, y_j) .

The three types of actions (in set A_i) a responder can take are: (i) *stay* in the current location (x_i, y_i) , (ii) *move* to the 8 neighbouring locations, or (iii) *complete* a task located at (x_i, y_i) . A joint action $\mathbf{a} = \langle a_1, \cdots, a_n \rangle$ is a set of actions where $a_i \in A_i$, one for each responder (a responder may just *stay* at its current position if it has no targets to rescue).

The transition function P is defined in more detail as: $P = P_r \times P_{p_1} \times \cdots \times P_{p_n} \times P_{t_1} \times \cdots \times P_{t_m}$ where:

- $P_r(s'_r|s_r)$ is the probability the radioactive cloud spreads from state $s_r \in S_r^G$ to $s'_r \in S_r^G$. It captures the uncertainty of the radiation levels in the environment due to noisy sensor readings and the variations in wind speed and direction.
- $P_{p_i}(s'_{p_i}|s,a_i)$ is the probability responder p_i transitions to a new state $s'_{p_i} \in S_{p_i}$ when executing action a_i . For example, when a responder is asked to go to a new location, she may not end up there because she is tired, gets injured, or receives radiation doses that are life threatening.
- $P_{t_j}(s'_{t_j}|s, \mathbf{a})$ is the probability of task t_j being completed. A task t_j can only be completed by a team of responders with the required types (Θ_{t_j}) located at the same position as t_j .

Now, if task t_j is completed (i.e., in $\mathtt{st}_j \in S_{t_j}$, the status \mathtt{st}_j is marked as "dropped off" and its position (x_j, y_j) is within a safe zone), the team will be rewarded using function R. The team is penalised if a responder p_i gets injured or receives a high dose of radiation (i.e., in s_{p_i} , the health level h_i is 0). Moreover, we attribute a cost to each of the responders' actions since each action requires them to exert some effort (e.g., running or carrying objects).

Give the above definitions, a policy for the MMDP is a mapping from states to joint actions, $\pi:S\to \mathbf{A}$ so that the responders know which actions to take given the current state of the problem. The quality of a policy π is measured by its expected value V^{π} , which can be computed recursively by the Bellman equation:

$$V^{\pi}(s^{\tau}) = R(s^{\tau}, \pi(s^{\tau})) + \sum_{s^{\tau+1} \in S} P(s^{\tau+1}|s^{\tau}, \pi(s^{t})) V^{\pi}(s^{\tau+1})$$
 (1)

where τ denotes the current time point and $\pi(s^{\tau})$ is a joint action given s^{τ} . The goal of solving the MMDP is to find an optimal policy π^* that maximises the expected value with the initial state s^0 , $\pi^* = \arg\max_{\pi} V^{\pi}(s^0)$.

Algorithm 1: Team Coordination Algorithm

```
Input: the MMDP model and the current state s.

Output: the best joint action \mathbf{a}.

// The task planning

1 \{t^i\} \leftarrow \text{compute the best task for each responder } p_i \in I;

2 foreach p_i \in I do

// The path planning

3 a_i \leftarrow \text{compute the best path to task } t^i;

4 return \mathbf{a}
```

At each decision step, we assume that the PA can fully observe the state of the environment s by collecting sensor readings of the radioactive cloud and GPS locations of the responders. Given a policy π of the MMDP, a joint action $\mathbf{a} = \pi(s)$ can be selected and broadcast to the responders (as mentioned earlier).

4 Team Coordination Algorithm

Unfortunately, our MMDP model results in a very large search space, even for small-sized problems. For example, with 8 responders and 17 tasks in a 50×55 grid, the number of possible states is more than 2×10^{400} . Therefore, it is practically impossible to compute the optimal solution. In such cases, we need to consider approximate solutions that result in high quality allocations. To this end, we develop an approximate solution using the observation that responders first need to *cooperatively* form teams (i.e., agree on who will do what), and that they can then *independently* compute the best path to the task. In our planning algorithm, we use this observation to decompose the decision-making process into a hierarchical structure with two levels: at the top level, a task planning algorithm is run for the whole team to assign the best task to each responder given the current state of the world; at the lower level, given a task, a path planning algorithm is run by each responder to find the best path to the task from her current location.

Furthermore, not all states of MMDPs are relevant to the problem (e.g., if a responder gets injured, she is incapable of doing any task in the future and therefore her state is irrelevant to other responders) and we only need to consider the reachable states given the current global state S of the problem. Hence, given the current state, we compute the policy online only for reachable states. This saves a considerable amount of computation because the size of the reachable states is usually much smaller than the overall state space. For example, given the current location of a responder, the one-step reachable locations are the 8 neighbouring locations plus the current locations, which are 9 locations out of the 50×55 grid. Jointly, the reduction is huge, from $(50 \times 55)^8$ to 9^8 for 8 responders. Another advantage of online planning is that it allows us to refine the model as more information is obtained or unexpected events happen. For example, given that the wind speed or direction may change, the uncertainty about the radioactive cloud may increase. If a responder becomes tired, the outcome of her actions may be liable to greater uncertainty.

The main process of our online hierarchical planning algorithm is outlined in Algorithm 1. The following sections describe the procedures of each level in more detail.

4.1 Task Planning

As described in Section 3.3, each responder p_i is of a specific type $\theta_i \in \Theta$ that determines which task she can perform and a task t can only be completed by a team of responders with the required types Θ_t . If, at some point in the execution of a plan, a responder p_i is incapable of performing a task (e.g., because she is tired or suffered a high radiation dose), she will be removed from the set of responders under consideration (that is $I \to I \setminus p_i$). This information can be obtained from the state $s \in S$. When a task is completed by a chosen team, the task is simply removed from the set (that is $T \to T \setminus t_k$ if t_k has been completed).

Now, to capture the efficiency of groupings of responders at performing tasks, we define the value of a team $v(C_{jk})$ that reflects the level of performance of team C_k in performing task t_j . This is computed from the estimated rewards the team obtains for performing t_j (as we show below). Then, the goal of the task planning algorithm is to assign a task to each team that maximises the overall team performance given the current state s, i.e., $\sum_{j=1}^m v(C_j)$ where C_j is a team for task t_j and $\{C_1, \cdots, C_m\}$ is a partition of I ($\forall j \neq j', C_j \cap C_{j'} = \emptyset$ and $\bigcup_{j=1}^m C_j = I$). In what follows, we first detail the procedure to compute the value of all teams that are valid in a given state and then proceed to detail the main algorithm to allocate tasks. Note that these algorithms take into account the uncertainties captured by the transition function of the MMDP.

4.1.1 Team Value Calculation

The computation of $v(C_{jk})$ for each team C_{jk} is challenging because not all tasks can be completed by one allocation (there are usually more targets than responders). Moreover, the policy after completing task t_j must also be computed by the agent, which is time-consuming given the number of states and joint actions. Given this, we propose to estimate $v(C_{jk})$ through several simulations. This is much cheaper computationally as it avoids computing the complete policy to come up with a good estimate of the team value, though we may not be able to evaluate all possible future outcomes. According to the central limit theorem, if the number of simulations is sufficiently large, the estimated value will converge to the true $v(C_{jk})$. This process is outlined in Algorithm 2.

In each simulation of Algorithm 2, we first assign the responders in C_{jk} to task t_j and run the simulator starting from the current state s (Line 4). After task t_j is completed, the simulator returns the sum of the rewards r and the new state s' (Line 4). If all the responders in C_{jk} are incapable of doing other tasks (e.g., suffered radiation burns), the simulation is terminated (Line 5). Otherwise, we estimate the expected value of s' using Monte-Carlo Tree Search (MCTS) [23] (Line 8), which provides a good trade-off between exploitation and exploration of the policy space and has been shown to be efficient for large MDPs. After N simulations, the average value is returned as an approximation of the team value (Line 10).

The basic idea of MCTS is to maintain a search tree where each node is associated with a state s and each branch is a task assignment for all responders. To implement MCTS, the main step is to compute an assignment for the free responders (a responder is free when she is capable of doing tasks but not assigned to any) at each node of the search tree. This can be computed by Equation 3 using the team values estimated by the UCB1 heuristic [2] to

⁴ Other methods such as sequential greedy assignment or swap-based hill climbing [37] may also be useful. However, they do not explore the policy space as well as MCTS.

Algorithm 2: Team Value Calculation

Input: the current state s, a set of unfinished tasks T, and a set of free responders I. **Output**: a task assignment for all responders.

```
1 \{C_{jk}\} \leftarrow \text{compute all possible teams of } I \text{ for } T;
2 foreach C_{jk} \in \{C_{jk}\} do

| // The N trial simulations
for i = 1 to N do

| (r,s') \leftarrow \text{simulate the process with the starting state } s until task k is completed by the responders in C_{jk};
if s' is a terminal state then

| v_i(C_{jk}) \leftarrow r;
else
| V(s') \leftarrow \text{estimate the value of } s' \text{ with MCTS};
| v_i(C_{jk}) \leftarrow r + \gamma V(s');
```

balance exploitation and exploration:

$$v(C_{jk}) = \overline{v(C_{jk})} + c\sqrt{\frac{2N(s)}{N(s, C_{jk})}}$$
 (2)

where $\overline{v(C_{jk})}$ is the averaged value of team C_{jk} at state s so far, c is a trade-off constant, N(s) is the visiting frequency of state s, and $N(s,C_{jk})$ is the frequency that team C_{jk} has been selected at state s. Intuitively, if a team C_{jk} has a higher average value in the trials so far or is rarely selected in the previous visits, it has higher chance of being selected in the next visit of the tree node.

As we assume that the type of a responder and the role requirements of each task are static, we can compute all possible team values offline. Therefore, in the online phase, we only need to filter out the teams for completed tasks and those containing incapacitated responders to compute the team set $\{C_{jk}\}$.

4.1.2 Coordinated Task Allocation

Given the team values computed above, we then solve the following optimisation problem to find the best solution:

$$\max_{x_{jk}} \sum_{j,k} x_{jk} \cdot v(C_{jk})$$
s.t. $x_{jk} \in \{0,1\}$

$$\forall j, \sum_{k} x_{jk} \leq 1 \qquad \text{(i)}$$

$$\forall i, \sum_{j,k} \delta_i(C_{jk}) \leq 1 \text{ (ii)}$$

where x_{jk} is the boolean variable to indicate whether team C_{jk} is selected for task t_j or not, $v(C_{jk})$ is the value of team C_{jk} , and $\delta_i(C_{jk})=1$ if responder $p_i\in C_{jk}$ and 0 otherwise. In the optimisation, constraint (i) ensures that a task t_j is allocated to at most one team (a task does not need more than one group of responders) and constraint (ii) ensures that a responder p_i is assigned to only one task (a responder cannot do more than one task at the same time). This is a standard Mixed Integer Linear Program (MILP) that can be efficiently solved using solvers (e.g., IBM CPLEX or lp_solve).

4.1.3 Adapting to Responder Requests

An important characteristic of our approach is that it can easily incorporate the preferences of the responders. For example, if a responder declines a task allocated to it by the planning agent, we simply filter out the teams for the task that contain this responder. By so doing, the responder will not be assigned to the task. Moreover, if a responder prefers to do the tasks with another responder, we can increase the weights of the teams that contain them in Equation 3 (by default, all teams have identical weights of 1.0). Thus, our approach is adaptive to the preferences of human responders.

4.2 Path Planning

In the path planning phase, we compute the best path for a responder to her assigned task. This phase is stochastic as there are uncertainties in the radioactive cloud and the responders' actions. We model this problem as a single-agent MDP that can be defined as a tuple, $\mathcal{M}_i = \langle S_i, A_i, P_i, R_i \rangle$, where: (1) $S_i = S_r^G \times S_{p_i}$ is the state space, (2) A_i is the set of p_i 's actions, (3) $P_i = P_r \times P_{p_i}$ is the transition function, and (4) R_i is the reward function. In this level, responder p_i only needs to consider the states of the radioactive cloud S_r^G and her own states S_{p_i} and her moving actions. Similarly, the transition function only needs to consider the spreading of the radioactive cloud P_r and the changes of her locations and health levels when moving in the field P_{p_i} , and the reward function only needs to consider the cost of moving to a task and the penalty of receiving high radiation doses. This is a typical MDP that can be solved by many existing solvers (see the most recent survey [29]). We choose Real-Time Dynamic Programming (RTDP) [3] because it is simple and particularly fits our problem, that is, a goal-directed MDP with large number of states. However, other approaches for solving large MDPs could equally be used here.

There are several techniques we use to speed up the convergence of RTDP. In our problem, the map is static. Thus, we can initialize the value function V(s) using the cost of the shortest path between the current location and the task location on the map, which can be computed offline without considering the radioactive cloud. This helps RTDP quickly navigate among the obstacles (e.g., buildings, water pools, blocked roads) without getting trapped in dead-ends during the search. Another speed up is also possible if, when traversing the possible states, we only consider the responder's current location and the neighbouring points. This will further speed up the algorithm where the main bottleneck is the huge state space.

4.3 Simulation Results

Before deploying our solution (as part of PA) to advise human responders, it is important to test its performance to ensure it can return efficient solutions on simulations of the real-world problem. Given there is no extant solution that takes into account uncertainty in team coordination for emergency response, we compare our algorithm with a greedy and a myopic method to evaluate the benefits of coordination and lookahead. For each method, we use our path planning algorithm to compute the path for each responder. In the greedy method, the responders are uncoordinated and select the closest tasks they can do. In the myopic method, the responders are coordinated to select the tasks but have no lookahead for the future tasks (Line 8 in Algorithm 2). Table 1 shows the results for a problem with 17

tasks and 8 responders on a 50×55 grid. As can be seen, our MMDP algorithm completes more tasks than the myopic and greedy methods (see Table 1). More importantly, our algorithm guarantees the safety of the responders, while in the myopic method only 25% of the responders survive and in the greedy method all responders are killed by the radioactive cloud. More extensive evaluations are beyond the scope of this paper as our focus here is on the use of the algorithm in a field deployment to test how humans take up advice computed by the planning agent PA.

Table 1 Experimental results for the MMDP, myopic, greedy algorithms in simulation.

	MMDP	myopic	greedy
No. of completed tasks	71%	65%	41%
No. responders alive at the end	100%	25%	0%

5 The AtomicOrchid Game

In this section we describe the AtomicOrchid game used to embed the planning agent in order to trial mixed-initiative coordination.

We adopt a serious mixed-reality games approach to counteract the limitations of computational simulations [15]. Our approach creates a realistic setting in the sense that participants are likely to experience physical exertion and stress through bodily activity and time pressure created by the distributed game setting, mirroring aspects of a real disaster setting [36]. This, in turn, provides greater confidence in the efficacy of behavioural observations regarding team coordination supported by a planning agent.

In more detail, AtomicOrchid is a location-based mobile game based on the fictitious scenario described in Section 3. First responders are assigned a specific type: medic, firefighter, soldier, or transporter. Their mission is to evacuate all four types of targets: victim (requires medic and fire-fighter), animal (requires medic and transporter), fuel (requires soldier and fire-fighter), or other resource (requires soldier and transporter). The first responders are supported by (at least) one person in a centrally located HQ room, and the planning agent PA that sends the next task (as described in the previous section) to the team of first responders. In what follows, we present the player interfaces used, the interactions with the planning agent, and the modelling of the radiation cloud in the game. A video of the operation of AtomicOrchid can be viewed at: http://bit.ly/lebNYty. [[COMMENT FROM HAIDM WORKSHOP REVIEW: the discussion of the atomic orchid game suggests that stress is created in the simulation. The human factors little distinguishes between stress and workload, so it would be accurate to say that the game induces workload but it's impact on stress is unknown or unverified. DONE. See above (JF).]] [[COMMENT FROM HAIDM: - explain why the responders can't see the expanding radioactivity cloud. This seems to be a big design error to have data that is not shared with people who rely on that data to make safe decisions. - DONE - see below]]

[[JOEL/WENCHAO: Please add back any text you think may help clarify the system and the key results and relationships to past work]]

5.1 Player Interfaces

First responders are equipped with a 'mobile responder tool' providing sensing and awareness capabilities in three tabs (geiger counter, map, messaging and tasks; see Figure 1). The first tab shows a reading of radioactivity, player health level (based on exposure), and a GPS-enabled map of the game area to locate fellow responders, the targets to be rescued and the drop off zones for the targets. The second tab provides a broadcast messaging interface to communicate with fellow first responders and the commander H. The third tab shows the team and task allocation dynamically provided by the agent PA that can be accepted or rejected. Notifications are used to alert both to new messages and task allocations.

Fig. 1 Mobile first responder and HQ interfaces.

iiiiiii HEAD H has at her disposal an 'HQ dashboard' that provides an overview of the game area, including real-time information of the players' locations (see Figure 1). The dashboard provides a broadcast messaging widget, and a player status widget so that the responders' exposure and health levels can be monitored. H can further monitor the current team and task allocations to individual responders by PA (by clicking on a button). Crucially, only H and PA have a view of the radioactive cloud, graphically depicted as a heatmap ('Hotter' (red) zones correspond to higher levels of radiation).

Importantly, the cloud is only known by the HQ, not field responders. In real world disaster operations, it is likely that HQ and field teams have different sources of information, and they have to communicate with available communication channels (e.g. text, messages). The design decision is aimed to simulate this characteristic of DR operation. ======H has at her disposal an 'HQ dashboard' that provides an overview of the game area, includ-

ing real-time information of the players' locations (see Figure 1). The dashboard provides a broadcast messaging widget, and a player status widget so that the responders' exposure and health levels can be monitored. H can further monitor the current team and task allocations to individual responders by PA (by clicking on a button). The radioactive cloud is graphically depicted as a heatmap ('Hotter' (red) zones correspond to higher levels of radiation). Crucially, only H can 'see' the entire cloud, while field responders are restricted to seeing a reading for their current location on their Geiger counters — this is a deliberate design choice to require frequent communication between HQ and field responders. $\@iditalign{c} \@iditalign{c} \@iditalign{c}$

5.2 System Architecture

AtomicOrchid is based on the open-sourced geo-fencing game MapAttack⁵ that has been iteratively developed for a responsive, (relatively) scalable experience. The location-based game is underpinned by client-server architecture, that relies on real-time data streaming between client and server. Client-side requests for less dynamic content use HTTP. Frequent events (e.g., location updates and radiation exposure) are streamed to clients to avoid the overhead of HTTP. In this way, first responders are kept informed in near real-time. Finally, to build the mobile app, we adapted the existing MapAttack Android app.

5.3 Integrating the Planning Agent

The planning agent PA takes the game status (i.e., positions of players, known status of the cloud, and messages received from players) as input and produces a plan for each responder for the current state. PA is deployed on a separate server. The AtomicOrchid server requests a plan from the agent via a stateless HTTP interface by transmitting the game status in JSON format. Polling (and thus re-planning) is triggered by two types of game events:

- Completion of task. On successful rescue of a target, a new plan (i.e., allocation of tasks to each responder) is requested from the agent.
- Explicit reject. On rejection of a task allocation by any of the allocated first responders, a new plan is requested. More importantly, the rejected allocation is, in turn, used as a constraint within the optimisation run by the planner agent (as described in Section 4.1.3). For example, if two responders, one medic and one soldier, were allocated a task and the medic rejected it, the planning agent would rerun the optimisation algorithm with the constraint that this medic should not be allocated this task. If another medic is free (and accepts) the soldier and this medic can go ahead and complete the task. Otherwise, a new plan is created for the soldier.

[[GOPAL: add architecture diagram showing how agent and human interact]]

Once a plan is received from PA, the AtomicOrchid game engine splits the plan for a given team into individual task allocations for each player and sends them to their mobile responder app. The app presents the task allocation in the task tab, detailing: i) the responder to team up with, ii) the allocated target (using target id), and iii) approximate direction of the target (e.g., north, east). Once a player accepts a task, an acknowledgement is sent to their teammate, while rejecting a task triggers a new assignment from PA.

5.4 Radiation Cloud Modelling

The radiation cloud diffusion process is modelled using the Smoluchowski drift-diffusion equation,

$$\frac{D \operatorname{Rad}(\mathbf{z}, \tau)}{D \tau} = \kappa \nabla^2 \operatorname{Rad}(\mathbf{z}, \tau) - \operatorname{Rad}(\mathbf{z}, \tau) \nabla \cdot \mathbf{w}(\mathbf{z}, \tau) + \sigma(\mathbf{z}, \tau)$$
(4)

where D is the material derivative, $Rad(\mathbf{z}, \tau)$ is the radiation cloud intensity at location $\mathbf{z} = (x, y)$ at time τ , κ is a fixed diffusion coefficient and σ is the radiation source(s) emission rate. The diffusion equation is solved on a regular grid defined across the environment with grid coordinates G (as defined in Section 3.3). Furthermore, the grid is solved at discrete time instances τ . The cloud is driven by stochastic wind forces which vary both spatially and temporally. These forces induce anisotropy into the cloud diffusion process proportional to the local average wind velocity, $\mathbf{w}(\mathbf{z}, \tau)$. The wind velocity is drawn from two independent Gaussian processes (GP), one GP for each Cartesian coordinate axis, $w_i(\mathbf{z}, \tau)$, of $\mathbf{w}(\mathbf{z}, \tau)$. The GP captures both the spatial distribution of the wind velocity and the dynamic process resulting from shifting wind patterns (e.g., short term gusts and longer term variations).

In our simulation, each spatial wind velocity component is modelled by an isotropic squared-exponential GP covariance function [41], K, with fixed input and output scales, l and μ , respectively (although any covariance function can be substituted),

$$K(\mathbf{z}, \mathbf{z}') = \mu^2 \exp{-(\mathbf{z} - \mathbf{z}')^T} \mathbf{P}^{-1} (\mathbf{z} - \mathbf{z}')$$

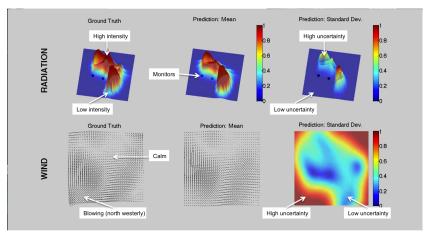

where ${\bf P}$ is a diagonal covariance matrix with diagonal elements l^2 . This choice of covariance function generates wind conditions which vary smoothly in both magnitude and direction across the terrain. Furthermore, as wind conditions may change over time we introduce a temporal correlation coefficient, ρ , to the covariance function. Thus, for a single component, w_i , of ${\bf w}$, defined over grid G at times τ and τ' , the wind process covariance function is, ${\rm Cov}(w_i({\bf z},\tau),w_i({\bf z}',\tau'))=\rho(\tau,\tau')K({\bf z},{\bf z}')$. We note that, when $\rho=1$ the wind velocities are time invariant (although spatially variant). Values of $\rho<1$ model wind conditions that change over time.

Using the above model, we are able to create a moving radiation cloud. This poses a real challenge both for the HQ (PA and H) and the responders on the ground, as the predictions they make of where the cloud will move to will be prone to uncertainty both due to the simulated wind speed and direction. Predictions of the clouds location are performed using a latent force model (LFM) [43,42]. The LFM is a Markov model that allows the future state of the cloud and wind conditions to be predicted efficiently from the current state. Predictions are computed using the Extended Kalman filter (EKF) which has a linear computational complexity with regard to the time interval the dynamics are predicted forward. The EKF estimates provide both the mean and variance of the state of the cloud and wind conditions. Figure 2 shows example cloud simulations for slow varying (i.e. $\rho=0.99$) and gusty (i.e. $\rho=0.90$) wind conditions. The left panes in each subfigure show the ground truth simulation obtained by sampling from the LFM. The middle panes show the mean of the cloud and wind conditions and the right panes show the uncertainty in the conditions.

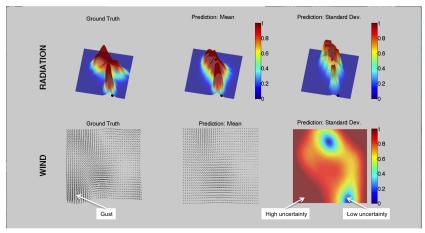

The radiation cloud can be monitored using a number of sensors on the ground that collect readings of the radiation cloud intensity and, optionally, wind velocity every minute of the game. These *monitor agents* can be at fixed locations or they can be mobile agents equipped with geiger-counters that inform the user and commander of the local radiation

⁶ The EKF accommodates the nonlinearities in the radiation dynamics expressed through equation (4).

intensity. The mobile agents can be directed to take measurements with greatest information gain in the radiation cloud intensity. The measurements can be folded into the EKF and this refines estimates of both the radiation cloud and wind conditions across the grid. Figure 2 shows the impact of such measurements on the uncertainty of the cloud and wind conditions. The current location of the monitors are shown as black dots in the upper row of panes in both subfigures. The right most panes show the relative uncertainty in both the cloud and wind conditions as a result of current and past measurements. Figure 2(a) shows slow varying wind conditions in which case the radiation cloud can be interpolated accurately using sparse sensor measurements and the LFM model. Alternatively, during gusty conditions the radiation cloud model is more uncertain far from the locations where recent measurements have been taken, as shown in Figure 2(b).

(a) Slowly varying wind conditions

(b) Gusty wind conditions

Fig. 2 Radiation and wind simulation ground truth and EKF estimates obtained using measurements from monitor agents (black dots). Left most panes are ground truth radiation and wind conditions, the middle panes are corresponding estimates and right most panes are state uncertainties: (a) invariant and (b) gusty wind conditions.

6 Field Trialling AtomicOrchid

We ran three sessions of AtomicOrchid with participants recruited from the local university to trial mixed-initiative coordination in a disaster response scenario. The following sections describe the participants, procedure, session configuration and methods used to collect and analyse quantitative and qualitative data.

6.1 Participants and Procedure

A total of 24 participants (17 males and 5 females) were recruited through posters and emails, and reimbursed with £15 for 1.5-2 hours of study. The majority were students. The procedure consisted of 30 minutes of game play, and about 1 hour in total of pre-game briefing, consent forms, a short training session, and a post-game group discussion.

At the end of the briefing, in which mission objectives and rules were outlined, responder types were randomly assigned to all participants (fire-fighter, medic, transporter, soldier). The HQ was staffed by a different member of the research team in each session in order to mimic an experienced H, while avoiding the same person running the HQ every time. Moreover, responders were provided with a smartphone and H with a laptop. The team was given 5 minutes to discuss a common game strategy. [[COMMENT FROM HAIDM: — the field trials appear to have a significant confounding factor, namely the lack of counterbalance in the different session PES. Many of the results, including the in table 2 and the subsequent paragraphs could be explained by a learning effect. Mthemaouthors state that the results are preliminary, so perhaps it is not too late to fix this apparent experiment design flaw. - DONE - attempted to address this further below (JF)]

First responders were then accompanied to the starting point within the designated game area, about 1 minute walk from headquarters. Once first responders were ready to start, H sent a 'game start' message. After 30 minutes of game play the first responders returned to the HQ where a group interview was conducted, before participants were debriefed and dismissed.

6.2 Game Sessions

We ran one session without PA, and two sessions with PA to be able to compare team performance in the two versions. Each session involved *different* sets of players (8 each). Thus, players were unique to a session to avoid learning effects between sessions. While we cannot rule out learning effects *within* sessions, we accept this as an integral part of working with humans in the real world.

We also ran a pilot study for each condition to fine tune game configuration. The 8 first responders in each session were randomly allocated a role so that the whole team had two of each of the four types of responders. The terrain of the 400x400 metre game area includes grassland, a lake, buildings, roads, footpaths and lawns. There were two drop-off zones and 16 targets in each session. There were four targets for each of the four target types. The target locations, pattern of cloud movement and expansion were kept constant for all game sessions. The pilot study showed that this was a challenging, yet not too overwhelming configuration of game area size, and number of targets to collect in a 30 min game session.

6.3 Data Collection and Analysis

We developed a log file replay tool to triangulate video recordings of game action with the timestamped system logs that contain a complete record of the game play, including responders' GPS location, their health status and radioactive exposure, messages, cloud location, locations of target objects and task status.

To assess how humans interact with each other and with PA, we focused on collecting data relevant to PA's task allocations and remote messages that are used to support coordination. In particular, we use speech-act theory [47] to classify messages sent between and among responders and H. We focus on the most relevant types of acts in this paper (which are also the most frequently used in AtomicOrchid):

- Assertives: speech acts that commit a speaker to the truth of the expressed proposition; these were a common category as they include messages that contain situational information.
- Directives: speech acts that are meant to cause the hearer to take a particular action,
 e.g. requests, commands and advice, including task and team allocation messages.

6.4 Results

Overall, 8 targets were rescued in the non-agent condition (Session A), and respectively 12 targets (Session B) and 11 targets (Session C) were rescued in the agent condition. Teams (re-)formed six times in session A, four times in session B and nine times in session C. Average player health after the game was much higher (more than double) for the agent-assisted sessions (80 for Session B and 82 for Session C) compared to the non-agent assisted session (40 in Session A) (see table [[TODO]]). In fact, one responder 'died' in Session A. This suggests that the agent's more conservative approach not to send field responders into 'harms way' paid off. Moreover, surprisingly this more conservative approach did also not result in less numbers of targets saved than with a perhaps less risk averse approach by HQ in Session A. This may probably be explained by more timely instructions by the agent, as these were generated automatically after a target had been dropped off.

PA dynamically re-planned 14 times in session B and 18 times in session C. In most cases, this was triggered when a target was dropped off in the safe zone (24 times) – as this frees up resources for PA to recompute an allocation. In the remaining cases, this was triggered by a player declining the agent's task allocation (8 times).

	no a	gent	agent			Total	
Speech acts	Session A		Session B		Session C		
	HQ	FR	HQ	FR	HQ	FR	
Directives	89	0	34	2	34	0	159
Assertives	33	6	26	16	24	16	121
Total	122	6	60	18	58	16	280

Table 2 Message classification. FR: First Responder.

[[COMMENT FROM HAIDM REVIEW: – the results should show something about the health status of the participants across the scenarios. Wenchao: can you add a table with the average (mean) health status for each session, including standard deviation]] Table 2 shows the remote message directives (mainly

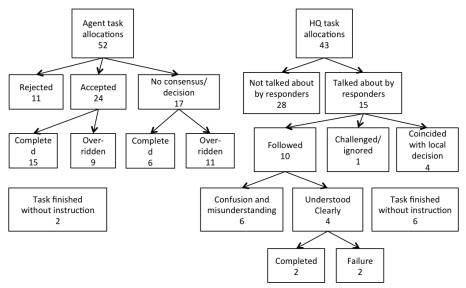

Fig. 3 How task allocations were handled by first responders in the version with agent (left), and without agent (right).

related to task allocation and execution) and assertives (mainly related to situational awareness) sent in the sessions. The following discussion draws on how these messages were handled to give a sense of mixed-initiative coordination in the game sessions.

In particular, Figure 3 shows how first responders handled task allocations in the agent and non-agent conditions. In the non-agent condition, the HQ commander sent 43 task allocation directives. Of these, the recipient first responders addressed only 15 messages (bringing them up in conversation). Of these 15, responders chose to ignore the instructions only once. The responders ignored the instruction because they were engaged in another task and did not want to abandon it. A further $4\,H$ instructions were consistent with a decision to rescue a certain target that had already been agreed locally by the responders. In the remaining 10 cases, first responders chose to follow the instructions. Although players were willing to follow H's instructions, they failed to correctly follow the instructions due to confusion and misunderstanding in the communication. In fact, only 2 instances of directives from H led to task completion. The first responders performed 6 rescue operations (tasks) without being instructed by H.

In contrast, when task allocation was handled by the agent (52 tasks allocated in two trials on average), responders explicitly accepted 24 tasks, of which they completed 15 successfully. Although there was either no response or no consensus between the responders (in 17 tasks allocated), they still completed 6 of these tasks successfully. In total, 20 task allocations were withdrawn by the agent as a result of re-planning.

In terms of task rejections, first responders rejected PA's task allocation 11 times in the agent version. All of the rejections happened when the task allocation would have *split existing teams*, or instructed responders to team up with *physically more distant responders*. In most cases (9 out of 11), they triggered re-planning by rejection and *adjusted the task allocation* to become consistent with the responder's current team. In the other two cases, the responders rejected the task allocation one more time before receiving the desired task

allocation. For accepted instructions, the average distance between suggested teammates was 12 metres. For rejected instructions, the average was 86 metres.

The results above show that the simple mechanism to get PA to re-plan (i.e., reject/accept) was more successful (more tasks completed and less confusion) than the open-ended interactions between H and the responders (that were open to confusion). Moreover, the fact that many of the rejections were due to the long distance to travel and teammate preference, implies that players chose to do the tasks they preferred rather than those deemed optimal by the agent. This indicates there may be an issue of trust in the agent, but also that it may be easier for a responder to impose (through a reject) such preferences on an agent (and indirectly to other team members) rather than expressing this to H or directly to teammates. It is also important to note that in the agent-assisted setting, H frequently monitored the allocation of tasks returned by the agent (57 clicks on 'show task' in UI responder status widget). Whereas 43 directives out of 68 in the non-agent session were task allocations, only 16 out of 68 were directly related to task allocations in the agent version. Out of these, H directly reinforced the agent's instruction 6 times (e.g., "SS and LT retrieve 09"), and complemented (i.e., added to or elaborated) PA's task allocation 5 times (e.g., "DP and SS, as soon as you can head to 20 before the radiation cloud gets there first"). H did 'override' PA's instruction in 5 cases.

In the agent version, most of H's directives (52 out of 68) and assertives (49 out of 51) focussed on providing situational awareness and routing the responders to avoid exposing them to radiation. For example, "NK and JL approach drop off 6 by navigating via 10 and 09.", or "Radiation cloud is at the east of the National College".

In summary, these results suggest three key observations with regard to human-agent coordination in the trial:

- First responders performed better (rescued more targets) and maintained higher health levels when supported by the agent. These results echo those obtained under simulation (see Section 4) and may reflect the better forward-planning capability of the planning agent compared to human responders.
- 2. Rejecting tasks was relatively frequently employed to trigger re-planning to obtain new task allocations aligned with responder preferences. In each case, the planning agent was able to adapt to provide an alternative that was acceptable to the responders. Without this facility we believe the responders would have chosen to ignore the plan. Task rejection seemed to be linked to changes to established teams, especially when members were relatively distant. Consequently, these kinds of allocations may need particularly support (e.g., explanation) or might be less preferentially selected by PA.
- 3. When task allocation was handled by PA, H could focus on providing vital situational awareness to safely route first responders around danger zones: thus demonstrating effective division of labour and complementary collaboration between humans and agents.

Given the above observation we argue that a planning agent for team formation should not only model the uncertainty in player behaviours and in the environment, but that interactional challenges also need to be addressed if such a technology is to be accepted in practice. In particular, we propose the following design guidelines for human-agent collaborations:

Adaptivity: our experiences suggest that planning algorithms should be designed to take in human input, and more importantly, be *responsive* to the needs of the users. As we saw in AtomicOrchid, players repeatedly requested new tasks and this would not have been possible unless our algorithm was computationally efficient but could dynamically assimilate updates, requests, and constraints dynamically. We believe this makes the algorithm more

acceptable to the users.

Interaction Simplicity: our agent was designed to issue simple commands (Do X with Y) and respond to simple requests (OK or Reject Task). Such simple messages were shown to be far more effective at guiding players to do the right task than the unstructured human communication in the non-agent assisted case that was fraught with inconsistencies and inaccuracies. In fact, we would suggest that agents should be designed with minimal options to simplify the reasoning users have to do to interact with the agent, particularly when they are under pressure to act.

Flexbile autonomy: the HQ dashboard proved to be a key tool for the HQ coordinator H to check and correct for the allocations of PA, taking into account the real-world constraints that the players on the ground faced. In particular, letting the human oversee the agent (i.e., "on-the-loop") at times and actively instructing the players (and bypassing the agent) at other times (i.e., "in-the-loop") as and when needed, was seen to be particularly effective. This was achieved by H without the agent defining when such transfers of control should happen (as in [46]) and, therefore, left the coordinator the option of taking control when she judged it was needed. Hence, we suggest that such deployed autonomous systems should be built for flexible autonomy. Specifically, interfaces should be designed to pass control seamlessly between humans and agents. [[-Gopal? Think this one's for you? (JF) the conclusions call for flexible autonomy, and this is somewhat supported by the algorithm and results. There are a few important limitations that the authors should discuss. For example, it is possible for responders to reject enough tasks that he mission becomes infeasible. How would such a problem be addressed? The solution to such problems is beyond the scpoe of the paper but the relevant limitations of the algorithms are not.]]

7 Conclusions

In this paper we developed a novel approach for integrating and evaluating agent-based coordination algorithms that allocate teams of emergency responders in dynamic and uncertain environments. In particular, we conducted field-trials of a task planning agent using a mixed-reality game called AtomicOrchid in order to focus on the issues that arise in human-agent collaboration in team coordination. Results from our study indicate the planning agent instructed players to carry out successful plans (outperforming a no-agent setting in terms of tasks completed and responders unharmed). The agent's ability to re-plan as per responders' preferences and constraints was particularly effective. Finally our results suggest that systems involving human-agent collaboration should be adaptive, involve simple interactions between humans and agents, and allow for flexible autonomy. Future work will look at running AtomicOrchid with expert responders and exploring different interactional arrangements of humans and agents, in particular where control may be distributed across the team.
